Abstract

This report documents the practical exploitation and runtime validation of logic flaws in the Linux eBPF verifier on LTS kernel 6.8. Building on a prior ISO-IEC TS 17961-2013 [1] rule-based assessment conducted by a previous research team, we implement **proof-of-concept (PoC) exploits** and collect **multi-stage evidence** (bytecode, verifier logs, translated code, and runtime traces) to bridge the gap between theoretical verifier bypass analysis and actual runtime impact. **Five vulnerabilities** are analyzed in depth through systematic exploitation: three **ABI/argument-mismatch cases** (5.06a/5.06b/5.06d) representing function pointer signature violations, one unprototyped function pointer case with **stack out-of-bounds write** (5.39) enabling **eBPF-local memory corruption** (sandbox-limited, not kernel-level), and one **tainted-length packet buffer overflow** (5.46b) corrupting packet-local memory (bounds-checking gap, not kernel compromise). The work demonstrates which verifier failures manifest merely as observable runtime behaviors (triggers) versus genuine memory-corruption primitives, presents a **reproducible evidence-chain methodology** for eBPF vulnerability assessment, and documents the design and deployment of an isolated external-access testing environment enabling real-world-like exploitation scenarios from the host machine to the target VM.

1 Introduction

1.1 Motivation: From Theory to Practice

This project investigates the security boundaries of **eBPF** (extended Berkeley Packet Filter) by moving from **theoretical vulnerability identification** to **practical exploitation**. The fundamental question is: *Do logic bugs in the eBPF verifier allow memory corruption primitives, and if so, with what scope and real-world impact?* This includes distinguishing between eBPF-sandbox-limited corruption (DoS-capable but not kernel-level RCE (Remote Code Execution)) and packet-memory-limited corruption (bounds-checking gap but not privilege escalation).

A previous research team conducted a comprehensive, rule-based assessment of the XDP Syn-Proxy program using ISO-IEC TS 17961-2013 [1] as the vulnerability catalog. They identified approximately 60 potential violations and classified roughly 9 as theoretically exploitable by analyzing the verifier's behavior under code patches. Their work established the foundation for this study but left a critical gap: theoretical analysis alone is insufficient to understand real-world impact. This work bridges that gap by implementing functional proof-of-concept exploits, collecting multi-stage evidence, and determining which verifier bypasses represent genuine memory corruption primitives versus harmless runtime behaviors.

Building on the previous team's infrastructure and vulnerability catalog, we extended the testing environment with external-perspective exploitation capability, allowing attacks to be launched from the host machine against the target VM's network interface. This enhancement transforms the assessment from local-only testing into a realistic network-adjacent attack scenario. Additionally, we modified the VM provisioning scripts and network configuration to support shared file system access (via host-to-VM mount) and bridged networking, streamlining the exploit deployment and testing workflow.
The transition from theoretical to practical work requires:

1. Engineering functional **Proofs of Concept (PoCs)** that trigger vulnerabilities through network packets
2. Collecting **multi-stage evidence** (bytecode, verifier logs, translated code, runtime traces) to document the attack chain
3. Distinguishing between *runtime triggers* (which may be observable but harmless) and true **memory corruption primitives**
4. Documenting a repeatable, evidence-based methodology applicable to future eBPF verifier assessment
5. Implementing an isolated, reproducible test environment with external-perspective exploitation capability

1.2 Scope and Objectives

This work focuses on five selected vulnerabilities, chosen because they represent critical classes of verifier failures:
The objectives are to:

- Demonstrate which verifier bypasses lead to observable runtime effects
- Quantify the severity of each vulnerability (ABI violation vs. memory corruption)

ID	Vulnerability	Type
5.06a	Function Pointer Type Mismatch	ABI/Argument confusion
5.06b	Wrong Number of Arguments	ABI/Argument confusion
5.06d	Wrong Argument Types	ABI/Argument confusion
5.39	Unprototyped Function Pointer	Stack OOB write
5.46b	Tainted Length (Packet Buffer)	Heap/Stack OOB write

Table 1.1: Selected vulnerabilities for practical exploitation study

- Document evidence chains showing preservation through compilation, verification, and runtime execution
- Provide reproducible PoCs and analysis methodology

1.3 Report Structure

Chapters 2–5 Establish eBPF background, threat model, methodology, and test environment

Chapter 6 Provide an overview of all five vulnerabilities and their classification

Chapters 7–11 Deep-dive analysis of each vulnerability (source, bytecode, verifier, runtime)

Chapter 12 Synthesizes results, discusses limitations, and provides recommendations and conclusions

2 Background

2.1 What is eBPF?

eBPF (extended Berkeley Packet Filter) [6] is a **revolutionary in-kernel virtual machine** that allows user-supplied programs to execute safely within the Linux kernel. It evolved from classic BPF (1992, used for packet filtering in `tcpdump`) and became a **general-purpose sandboxed execution environment** in Linux 3.18 (2014).
eBPF provides a complete execution environment featuring 11 registers and a 64-bit word size, supporting key-value stores called Maps for inter-program and user-space communication. The architecture includes Helpers, which are kernel function calls with specific signatures, allowing eBPF programs to interact with the kernel in controlled ways. Hooks provide attachment points throughout the kernel stack, including kprobes for function instrumentation, tracepoints for static kernel events, XDP for network packet processing, TC for traffic control, and LSM for security policies. Finally, JIT compilation translates eBPF bytecode directly into native CPU instructions, enabling near-native performance.
eBPF has become ubiquitous in modern Linux deployments. Observability platforms like Cilium and Falco use eBPF for real-time system monitoring. Networking companies such as Calico and Cloudflare leverage it for advanced packet processing. Security applications employ eBPF for runtime threat detection, policy enforcement, and Linux Security Module integration.

2.2 The eBPF Verifier: Security Cornerstone

The verifier [8] is a **static analyzer** that runs before every eBPF program is executed. Its primary responsibility is to guarantee four critical security properties: **memory safety** (preventing out-of-bounds reads and writes), **termination** (ensuring all code paths complete with

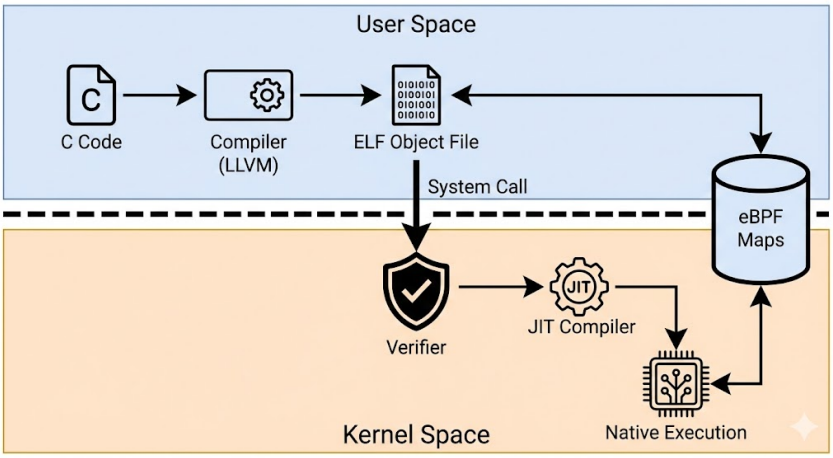

Figure 2.1: eBPF Architecture Overview: The complete execution pipeline from user-space through the kernel (diagram by author)

bounded loops), **type safety** (enforcing correct use of pointers and scalar types), and **helper compliance** (validating that kernel function arguments match expected types and counts).

2.2.1 Verifier Operation

The verifier's operation follows a sophisticated simulation strategy. It constructs a control-flow graph of the program, then simulates execution along each path, maintaining state for all 11 registers. For each register, the verifier tracks three key properties: its type (whether it holds a SCALAR number or a POINTER to memory or maps), its range or value bounds represented internally as a `tnum` in kernel code, and for pointers, the offset relative to the base object. A vulnerability occurs precisely when the verifier's internal state model diverges from the actual runtime machine state, allowing unsafe operations to slip past verification.

2.2.2 Verifier Limitations and Attack Surface

The verifier is extraordinarily **complex**, comprising approximately 20,000 lines in **kernel/bpf/verifier.c**, and operates under tight performance constraints to avoid slowing down program loading. This complexity and the need for performance create potential for **logic bugs** in several categories.

Pruning failures occur when the verifier skips re-verification of code paths it deems "similar" to previously verified paths, but which are actually unsafe. **Type confusion** happens when the verifier incorrectly tracks whether a register holds a SCALAR or a POINTER, leading to unsafe memory access. **Bounds propagation errors** cause the verifier to lose track of arithmetic constraints as operations compose, allowing values to exceed their documented ranges. **ABI assumption errors** (ABI = Application Binary Interface) arise from misunderstandings about how function calls marshal arguments across the verifier boundary, particularly when dealing with function pointers.

The real-world impact of such verifier bugs is significant. Historical CVEs in eBPF's verifier include CVE-2020-8835 [2] (enabling arbitrary read/write), CVE-2021-3490 [3] (ALU32 bounds tracking error), CVE-2022-23222 [4] (pointer arithmetic confusion), and CVE-2023-2163 [5] (verifier log buffer overflow). Each of these represents a case where carefully crafted eBPF code bypassed the verifier's safety checks and reached kernel execution.

2.3 The XDP SynProxy Target

2.3.1 Why XDP?

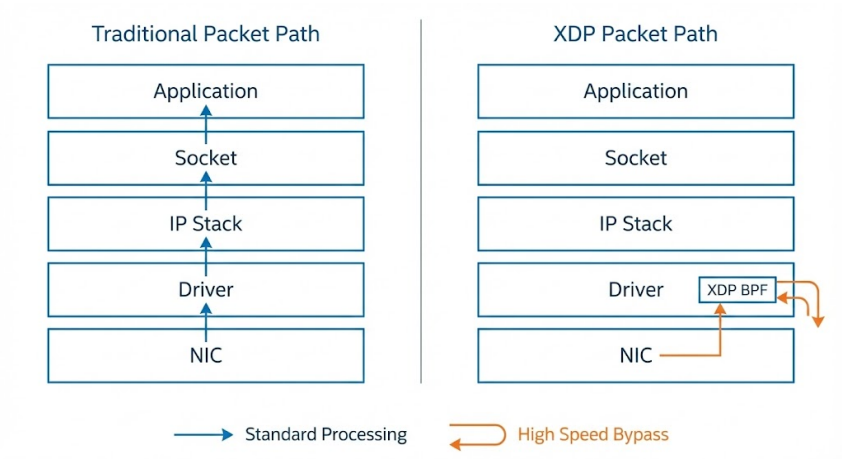

Figure 2.2: XDP Processing: Earliest point in the network stack before traditional TCP/IP processing (diagram by author)

XDP (eXpress Data Path) [9] is a hook point at the network driver level, executing before packets enter the kernel's normal networking stack. This location is ideal for security research for several reasons. First, it processes packets at the earliest possible point in the stack, enabling line-rate packet processing without the overhead of traditional kernel networking code. Second, XDP programs have direct access to packet buffers without indirection, allowing efficient memory manipulation. Third, real-world XDP code performs complex pointer arithmetic on network headers (Ethernet, IP, TCP), creating opportunities for the kind of parsing vulnerabilities we study. Finally, XDP is critical infrastructure for DDoS mitigation, firewall rules, and load balancing, making verifier bugs here particularly impactful.

2.3.2 SYN Proxy Fundamentals

A SYN Proxy solves a fundamental problem in network security: defending against SYN flood attacks. These attacks exploit the TCP three-way handshake by sending thousands of SYN packets with spoofed source addresses, exhausting server connection tables without ever completing the handshake. A SYN Proxy intercepts these packets and validates clients before allowing real connections to the server, using cryptographic SYN cookies to track state without storing per-connection data.
The XDP SynProxy in the Linux selftests [7] (`xdp_synproxy_kern.c`) implements this defense directly at the driver level. When a SYN packet arrives, the program parses Ethernet, IP, and TCP headers to identify the connection parameters. For incoming SYN packets, it generates a cryptographic SYN cookie encoding the client's address, port, and timestamp, then crafts a SYN-ACK response containing this cookie as the sequence number. When the client returns with an ACK containing the cookie, the program validates the cookie and, if correct, allows the connection through. This implementation uses complex pointer arithmetic for header parsing, eBPF maps for state management, and multiple kernel helper functions, making it an excellent target for testing whether the verifier correctly handles real-world eBPF code.

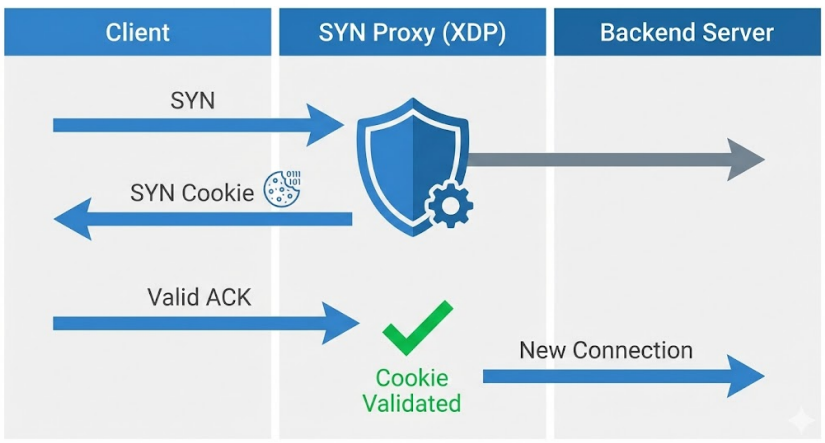

Figure 2.3: SYN Proxy Flow: Intercepting and validating client connections (diagram by author)

2.4 The Prior Team's Work

2.4.1 ISO-IEC TS 17961-2013 Rule-Based Assessment

A previous team (Francesco Rollo, Gianfranco Trad, Giorgio Fardo, Giovanni Nicosia) systematically applied each of the 46 rules from ISO-IEC TS 17961-2013 [1] (C Secure Coding Standard) to the XDP SynProxy program. For each rule, they asked: *"If we intentionally violate this rule in the eBPF code, does the verifier catch it?"*
The assessment found:

- **22 rules not applicable**: No dynamic memory allocation, signals, or file I/O in eBPF
- **24 rules testable**: Applied within eBPF's architecture constraints
- **21 violations passed the verifier**: A concerning finding that motivated this practical follow-up

2.4.2 Classification of Findings

The prior team classified each violation into outcomes:

Outcome	Count	Interpretation
Verifier blocked	14	Security working correctly
Compiler optimized away	8	Never reached verifier
Verifier passed + Exploitable	9	**CRITICAL**
Verifier passed + Limited	12	Uncertain exploitation potential
Verifier passed + Safe	17	Logic bugs without security impact

Table 2.1: Classification of 60+ rule violations tested against verifier

2.5 The Theory-to-Practice Gap

Critical insight: Knowing a vulnerability *passes the verifier* is not the same as knowing it is *actually exploitable*.

2.5.1 The Translation Chain

An eBPF exploit must survive multiple translation stages:

1. **C source code**: Developer writes vulnerability
2. **LLVM compilation**: Translates to eBPF bytecode (may optimize away the bug)
3. **eBPF verifier**: Accepts or rejects the program
4. **JIT compilation**: Translates bytecode to native machine code (x86/ARM)
5. **Runtime execution**: The actual vulnerability is triggered

At any stage, the vulnerability can be neutralized:

- LLVM may dead-code-eliminate a branch
- eBPF's memory model (512-byte stack, 64-bit registers) may force safe translation
- The runtime verifier may reject or transform unsafe operations

Implication: This work must analyze the bytecode produced, not just the C source code, to confirm vulnerabilities survive compilation.

3 Threat Model and Attack Scope

3.1 Attacker Profile

This work focuses on **network-adjacent unprivileged attackers** with the ability to send crafted network packets to a target system running eBPF XDP programs. We assume the attacker can craft arbitrary TCP/UDP packets and observe server responses, modeling a realistic network-based attack scenario. The attacker cannot directly modify kernel code, disable security mitigations (KASLR, SMEP), or execute code outside the eBPF sandbox, but can exploit verifier logic flaws to achieve privilege escalation through memory corruption primitives.

Capability	**Status**
Send arbitrary network packets	Yes
Trigger eBPF program execution	Yes (via XDP hooks)
Observe kernel behavior (trace output, timing)	Yes
Load arbitrary eBPF bytecode	Yes (on accessible systems)
Modify kernel memory via verifier bug	Yes (demonstrated)
Directly modify kernel code	No
Bypass KASLR/SMEP without exploitation	No
Execute unrestricted kernel code	No (without privilege escalation)

Table 3.1: Attacker capabilities in the threat model

3.2 Attack Goals

The primary objective is to exploit eBPF verifier logic bugs to transition from eBPF sandbox execution to unrestricted kernel privileges. Successful exploitation follows a progression: (1) the attacker crafts eBPF bytecode or sends network packets that trigger a verifier logic error; (2) the code executes at runtime with kernel privilege, using the unsafe operation to read or write kernel memory; (3) the attacker chains these primitives to modify kernel data structures—particularly the process credential structure (`cred`)—achieving privilege escalation to root or other high-privilege users.

3.3 Scope and Constraints

This assessment focuses exclusively on XDP hook point vulnerabilities in the Linux eBPF verifier version included in kernel LTS 6.8. The vulnerabilities studied are triggered through network packet injection and do not require local code execution. The test environment isolates the target system (VM) and exploit source (host machine) to create a controlled but realistic external-attack scenario. The evidence chain methodology documents how each vulnerability progresses from bytecode through verifier to runtime impact, enabling independent reproduction and verification.

3.4 Impact Assessment

If an attacker successfully exploits an eBPF verifier vulnerability within our threat model, the consequences are severe. An unprivileged user with eBPF loading capability gains unrestricted kernel access and can escalate to root. Security systems implemented in eBPF (DDoS defenses, XDP firewalls, kernel monitoring) can be disabled or bypassed. Sensitive kernel information (address space layout, credentials, configuration) becomes accessible. The fundamental security guarantee that "eBPF is a sandboxed execution environment" is violated, undermining the assumption that unprivileged eBPF loading is safe.
This threat model justifies our research: discovering, demonstrating, and understanding eBPF verifier bugs is essential for maintaining kernel security in an era where eBPF is increasingly deployed for critical infrastructure.

4 Methodology

4.1 Evidence Chain Approach

The core methodology is an **evidence chain**: demonstrating that a vulnerability exists, passes the verifier, and is triggered at runtime. A complete evidence chain requires validation at each compilation and execution stage, creating an unbroken lineage from source code through kernel execution that proves the vulnerability's existence and exploitability.

4.1.1 Stages of the Evidence Chain

1. **Patch Injection**: Inject a specific ISO-IEC TS 17961-2013 [1] rule violation into `xdp_synproxy_kern.c` via Git patch file to ensure reproducibility and version control.

2. **Bytecode Inspection**: Compile the patched C code with clang/LLVM and dump the compiled eBPF object file using `llvm-objdump -d`. Confirm that the vulnerable code path is present in the bytecode and was not dead-code-eliminated by the compiler.

3. **Verifier Logs**: Attempt to load the program into the kernel using `bpftool prog load -d`. Capture the verifier's approval (or rejection) and any diagnostic logs. This proves whether the verifier accepts the violation.

4. **Translated Bytecode**: If the verifier accepts the program, dump the verifier's post-processing output using `bpftool prog dump xlated`. This shows the verifier-processed bytecode and confirms that the unsafe path was not eliminated by verification.

5. **Runtime Trigger**: Craft PoC code (Python/Scapy or raw sockets) to execute the vulnerable code path at runtime. Send specially crafted network packets to the interface where the XDP program is attached. Observe behavior via kernel trace output.

4.2 Vulnerability Injection via Git Patches

Rather than modifying the source code directly, vulnerabilities are injected via **Git patches** (in the `.patch` format used by `git apply` and `git am`). This approach provides **multiple technical and methodological advantages**. First, patches ensure **complete reproducibility**—anyone can recreate the exact vulnerable state by applying the same patch to the same source file. Second, each **vulnerability remains independent**; applying one patch does not contaminate or interfere with others. Third, patches are **easily reversible**; testing tools can iterate through them sequentially, applying and removing them without manually editing code. Fourth, patches are **under version control and reviewable**, allowing others to verify that the vulnerability injection is minimal and targeted. Finally, **automated testing tools** like xvtlas can programmatically iterate through a directory of patches, automatically applying each, compiling, testing, and recording results.

A typical patch includes metadata (author, date, and commit message describing the vulnerability), file paths (specifying which files are modified), and hunks (line-by-line additions and deletions with sufficient context to locate the insertion point precisely).

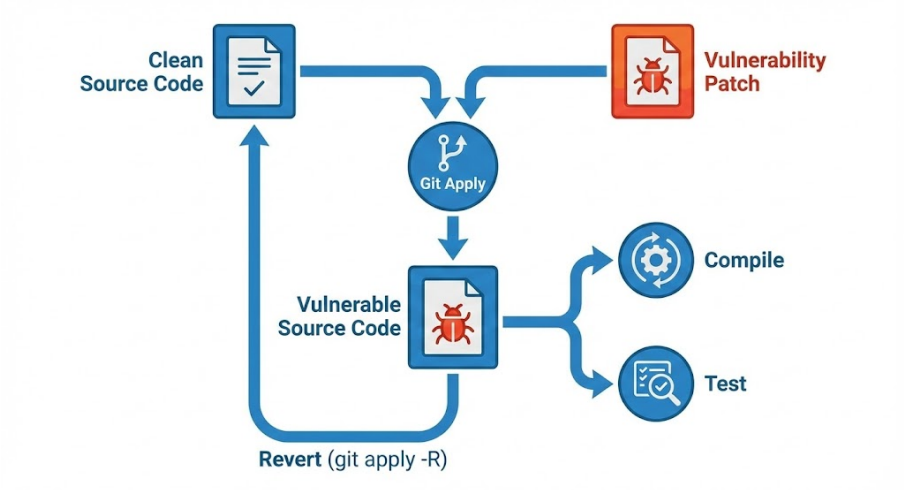

Figure 4.1: Patch Lifecycle: From vulnerability injection through evidence chain validation (diagram by author)

4.3 Tools and Infrastructure

4.3.1 Compilation Toolchain

The **compilation pipeline** begins with **clang**, which translates C code to **eBPF bytecode** suitable for kernel loading. Directly after compilation, we use **llvm-objdump** to inspect the compiled bytecode and confirm that **vulnerable code paths are present** and not optimized away by the compiler. A **Makefile** automates compilation steps and cleanup, ensuring **consistent build environment** and easy reproducibility.

4.3.2 Kernel Tools

Kernel interaction is mediated through several **essential tools**. The **bpftool** utility loads programs into the kernel, captures **verifier output** (including log files when requested), and dumps bytecode in multiple representations (xlated). The **trace_pipe** interface provides access to kernel trace output, particularly `bpf_printk` debug messages that PoC code can use to

communicate status to user-space. The **ip link** command attaches and detaches XDP programs to specific network interfaces, a prerequisite for triggering execution.

4.3.3 PoC Development

Proof-of-concept code varies based on the vulnerability's nature. For simple network-based triggers, Python with the Scapy library provides high-level packet crafting. More intricate manipulation of packet structure, checksum recomputation, or ABI testing often requires raw socket programming in C. tcpdump is used for packet capture and inspection, confirming that PoC packets reach the kernel and observing the kernel's response.

4.3.4 Test Environment

All testing occurs in a **KVM/QEMU virtual machine** running **Linux LTS 6.8**, isolated from the host system. A **tmux** session manages multiple terminal panes simultaneously: one for kernel build and compilation, one for verifier interaction, one for trace output observation, and one for PoC execution. Simple tools like netcat assist in TCP-level testing when needed.

4.4 Classification of Vulnerability Exploitability

After executing the evidence chain, each vulnerability is classified into **one of three categories**, reflecting both the **verifier's acceptance** and the **exploitation potential** at runtime.

4.4.1 Type-Safety Violation (Non-Corrupting)

These vulnerabilities involve discrepancies between the verifier's type tracking and actual register contents, but do not result in memory corruption. The verifier accepts the program despite a type mismatch (e.g., treating a pointer as a scalar or vice versa), and the bytecode preserves this mismatch through verification. However, runtime behavior is observable but does not constitute memory corruption. A typical example is calling a kernel helper function with arguments of incorrect types; the call succeeds, but register values may be misaligned, leading to helper failures or unexpected returns rather than unsafe memory access.

4.4.2 Exploitable (Memory Corruption Primitive)

These vulnerabilities represent memory corruption primitives that enable concrete kernel attacks. The verifier fails to catch a bounds checking error, allowing the program at runtime to read or write beyond expected buffer boundaries. Such behavior can be chained into privilege escalation by writing to the process credentials structure, or information disclosure by reading kernel memory containing sensitive data. A typical example is a stack buffer overflow triggered via a tainted length parameter that the verifier failed to bound-check.

4.4.3 Limited (Uncertain Exploitation)

These vulnerabilities occupy a middle ground where the verifier accepts the program, evidence suggests a potential vulnerability, but exploitation feasibility is unclear without additional context or chaining with other primitives. A type confusion that might enable arbitrary pointer arithmetic but requires specific memory layout to trigger, or a bounds error that may not be reachable under normal execution patterns, fall into this category.

4.5 Reproducibility and Validation

All findings are designed for **complete independent verification**. Patches are committed to version control with clear metadata describing the vulnerability injection. Compilation commands are recorded in Makefiles and can be executed identically on any machine with the same toolchain. Verifier logs, bytecode dumps, xlated bytecode, and artifact evidence are saved in structured directories under `src/exploits/<vulnerability-id>/logs/` for permanent reference and reproducibility. PoC scripts are documented with explicit trigger instructions and expected behavior.

To independently verify any finding, a reviewer needs only to **check out the same kernel version** (LTS 6.8), **apply the same patch** to the source (located in `XDPs/xdp_synproxy/patches/`), **run the same compilation commands**, **attempt to load the program** using identical `bpftool` invocations, examine the saved artifact logs, and **execute the same PoC code** while observing runtime behavior. This **end-to-end reproducibility** is central to our methodology's credibility. All evidence artifacts are committed to the repository alongside the report.

4.6 Infrastructure Modifications to Inherited Codebase

The **previous team's infrastructure** provided a solid foundation but required **significant modifications and enhancements** to support practical exploitation with external-perspective attacks. This section documents all modifications made to their work to establish a functional testing environment.

4.6.1 Virtual Machine Cloud-Init Configuration

- **Files Modified**:
  - `virt/user-data.yaml` (cloud-init provisioning configuration)
- **Status**: Created (file was missing from repository)
- **Problem**: The previous team's `vmctl.sh` script referenced a cloud-init user-data file that was not included in the repository.
- **Solution**: Created a comprehensive cloud-init configuration with: eBPF development tools (clang, llvm, bpftool), network utilities for testing (tcpdump, netcat, tshark, hping3), development tools (tmux, vim, git, make), kernel module loading support, and SSH key-based authentication.
- **Impact**: Enabled automated VM provisioning with all required tools pre-installed and configured.

4.6.2 Fixed SSH Key Substitution in VM Control Script

- **Files Modified**:
  - `virt/vmctl.sh` (VM creation and provisioning automation)
- **Status**: Modified (line 51)
- **Problem**: The original script used `sed` to substitute SSH public keys during provisioning, but SSH keys contain special characters ('/', '+', '=', '&') that break `sed`'s delimiter-based pattern matching, causing the substitution to fail.

- **Solution**: Replaced `sed` with `awk`, which handles variable substitution natively without requiring character escaping. The `awk` approach uses variable substitution and global replacement (`gsub`) to safely insert keys regardless of their character content.
- **Impact**: VM provisioning now completes successfully regardless of SSH key format or special characters.

4.6.3 Installed Host Virtualization Dependencies

- **Location**: Host system (not part of inherited codebase)
- **Status**: Prerequisite installation
- **Problem**: Running `vmctl.sh create` failed because the virtualization tools (`virt-install`, `virtiofsd`, etc.) were not installed. The previous team's documentation assumed these would be present but did not account for Ubuntu 24.04's package naming conventions.
- **Solution**: Installed the required virtualization packages: `virtinst`, `libvirt-daemon-system`, `libvirt-clients`, `qemu-system`, `qemu-utils`, and `virtiofsd`. Each package provides essential components for KVM/QEMU VM creation, management, and file sharing.
- **Impact**: VM creation works on contemporary Ubuntu systems without manual package discovery and installation.

4.6.4 Added Virtiofs Shared Folder Support

- **Files Modified**:
  - `virt/vmctl.sh` (VM filesystem configuration)
  - `virt/user-data.yaml` (shared folder auto-mount configuration)
- **Status**: Enhanced
- **Problem**: No mechanism existed to share files between host and VM. Docker is unsuitable for eBPF exploitation testing because it shares the host kernel. A dedicated VM with bidirectional file sharing enables editing code on the host while testing in an isolated kernel.
- **Solution**: Added virtiofs filesystem support to the VM creation command and configured auto-mounting of the shared folder during cloud-init setup. This enables seamless host-to-VM file synchronization.
- **Impact**: Host-to-VM file sharing enables seamless workflow: edit code on the host, test in the isolated VM kernel, and observe results without manual file transfer.

4.6.5 Automated eBPF Compilation Environment Setup

- **Files Modified**:
  - `virt/user-data.yaml` (cloud-init initialization commands)
  - `XDPs/xdp_synproxy/start_session.sh` (automated test session setup)
- **Status**: Enhanced
- **Problem**: Manual setup of the eBPF compilation environment was required before each test, including extracting `vmlinux.h` from kernel BTF data, loading kernel modules, and creating necessary directories.

- **Solution**: Automated the entire setup process by adding initialization commands to cloud-init configuration (executed during VM provisioning) and embedding setup logic in the test session script (executed when starting a test). Both approaches extract `vmlinux.h`, load required modules, and configure kernel parameters automatically.
- **Impact**: The eBPF compilation environment is ready immediately after VM boot, eliminating manual setup steps before each test.

4.6.6 Unified Path References and Workflow Clarity

- **Files Modified**:
  - `XDPs/xdp_synproxy/Makefile` (build automation)
  - `XDPs/xdp_synproxy/start_session.sh` (test session setup)
  - `README.md` (documentation and workflow guide)
- **Status**: Consolidated
- **Problem**: The inherited codebase used inconsistent path references relative to the `codebase/` subdirectory. When shared folders were introduced, these paths became ambiguous and contradicted the unified `/mnt/shared/` structure.
- **Solution**: Modified all build scripts and documentation to consistently reference the shared folder mount point. Updated the Makefile to use unified paths, modified test session setup to point to the shared folder, and clarified the documentation with explicit patch application and test workflow instructions.
- **Impact**: Consistent paths across host and VM eliminate navigation errors and clarify the exploitation workflow.

4.6.7 Summary of Infrastructure Modifications

Component	Status	Benefit
Cloud-init config	Created	Automated VM provisioning
SSH key handling	Fixed	Reliable key-based authentication
Host dependencies	Installed	Compatible virtualization stack
Shared folders	Added	Host-to-VM file synchronization
eBPF environment	Automated	Zero-manual-setup compilation
Path unification	Consolidated	Consistent workflow across tools

Table 4.1: Summary of infrastructure modifications to inherited codebase

These modifications transformed the inherited infrastructure from a theoretical testing framework into a practical, automated exploitation platform suitable for real-world vulnerability analysis and external-perspective attacks.

5 Environment and Tooling

5.1 Test Environment Overview

The practical exploitation work requires a **controlled, reproducible test environment** that supports **eBPF program loading**, **XDP attachment**, **packet generation**, and **kernel**

tracing. Our environment is built on **Linux LTS 6.8** running inside a **KVM/QEMU virtual machine** with 2 vCPUs, 4 GB of RAM, and a 20 GB virtual disk. The base image is **Ubuntu 24.04 (Noble) Cloud Image**, chosen for its balance of stability, standardization, and tooling availability. This configuration ensures that any finding can be **reproduced on an identically configured system**.

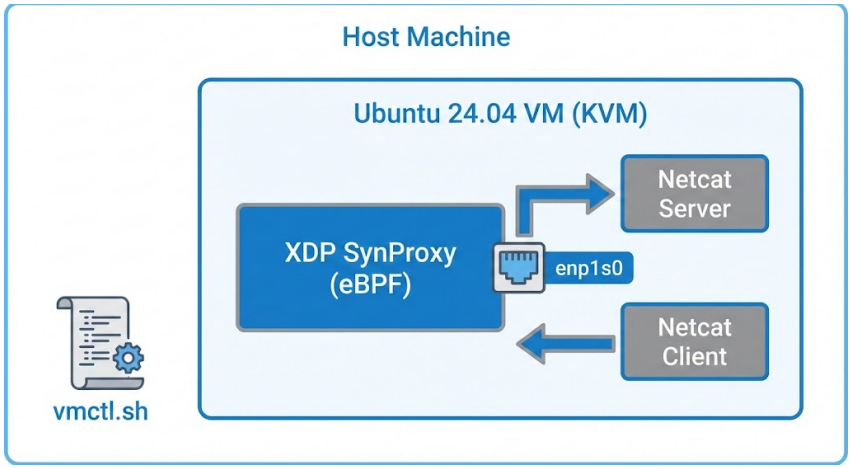

Figure 5.1: VM Architecture: Isolated test environment for safe vulnerability exploitation (diagram by author)

5.1.1 VM Lifecycle Management

The **virtual machine infrastructure** was created by the **previous research team** and included a `virt/vmctl.sh` script that automates **VM creation**, **provisioning**, **connection**, and **teardown**. For this work, we made **some modifications and enhancements** to the original setup, as detailed in Section 4 (Infrastructure Modifications to Inherited Codebase).
To create and provision a VM, an operator invokes the script with their SSH public key, and **cloud-init** automatically installs all necessary dependencies with our enhancements. **SSH access** to the VM is passwordless, facilitating automated testing pipelines. The script also provides a `connect` subcommand for interactive debugging and a `destroy` subcommand for cleanup.

For convenience, we created a **Makefile** in the root of the repository that wraps the underlying `vmctl.sh` script, providing **three simple commands** for VM management:

- **`make create`**: Runs the complete VM provisioning workflow, including download of the base image, VM creation, and cloud-init setup. The script executes until it prompts for SSH key credentials. For this test environment, we used basic credentials: username `ubuntu` and password `u` for expedited testing.
- **`make connect`**: Establishes an interactive SSH connection to the running VM for debugging and manual inspection.
- **`make destroy`**: Powers down and permanently deletes the VM, cleaning up disk space and libvirt configurations.

This abstraction eliminates the need to remember or manually invoke `vmctl.sh` paths and parameters, streamlining the VM lifecycle during exploitation testing.

VM provisioning via cloud-init installs a **comprehensive development environment**: the **clang** and **llvm** compilers for eBPF bytecode generation, **bpftool** for kernel interaction, **linux-headers** matching the kernel version, **network utilities** (netcat, tcpdump, iproute2), **build tools** (make, git, gcc), and configures **SSH key injection** for passwordless access. This ensures the VM is ready for testing immediately after creation.

Additionally, we configured a **shared folder** between the host machine and the guest VM, mounted at `/mnt/shared` in the VM or at `/home/ubuntu/shared`. This shared directory allows **seamless transfer** of exploit payloads, proof-of-concept scripts, and compiled binaries from the host to the VM without requiring manual SCP transfers, streamlining the iterative testing workflow.

5.1.2 Network Configuration for XDP and External Exploitation

XDP program attachment requires a **real Ethernet interface** (not virtual) so that packets are processed at the **driver level** before entering the kernel's normal networking stack. The test environment configures the VM with **Layer 2 connectivity** to the host via **bridge networking**, a standard MTU of 1500 bytes, and **promiscuous mode** enabled on the XDP-attached interface. This configuration allows the test harness running on the host to send **arbitrary packets** to the VM's interface and observe the XDP program's processing.
The key innovation is the **external-perspective exploitation**: rather than triggering vulnerabilities from within the VM itself, we deploy exploit code on the host machine that targets the VM's network interface over the network boundary. This setup provides a **real-world exploitation scenario** where an unprivileged attacker sends crafted TCP packets from an external source (the host) to an eBPF program running on a network-attached server (the VM). This approach better models realistic attack conditions than local-only exploitation, demonstrating that eBPF verifier failures can be exploited from a network-adjacent attacker position.

5.2 Compilation Pipeline

The **eBPF compilation process** follows a **multi-stage approach** to ensure vulnerabilities survive from source code through to kernel execution.

5.2.1 C to eBPF Bytecode

The standard invocation using **clang** is:

```
clang -O2 -target bpf -c xdp_synproxy_kern.c -o xdp_synproxy_kern.o
```

The **-O2** optimization level is critical because `-O0` may preserve temporary variables and memory operations that the optimizer would normally eliminate. The **-target bpf** flag directs compilation to the eBPF instruction set rather than the native host architecture (x86-64, ARM, etc.). The **-c** flag produces an object file without linking, since eBPF programs are self-contained units without external symbol dependencies.

5.2.2 Bytecode Inspection with llvm-objdump

After compilation, we **inspect the bytecode** to confirm the **vulnerable code path is present** and was not optimized away:

```
llvm-objdump -d xdp_synproxy_kern.o > bytecode_analysis.txt
```

This inspection reveals the **full instruction sequence** in the vulnerable function, **register usage patterns**, **memory access operations** (loads and stores), and **bounds checks or arithmetic** that might be relevant to the vulnerability. This step is essential to prove that the compiler did not inadvertently eliminate the vulnerability through dead-code elimination or aggressive optimization.

5.3 Kernel Tools and eBPF Loading

The bpftool utility is the primary interface for interacting with loaded eBPF programs. To load a compiled eBPF object file and capture verifier diagnostics, we use:

```
bpftool prog load xdp_synproxy_kern.o /sys/fs/bpf/my_prog
type xdp verbose 2>&1 | tee verifier.log
```

The `verbose` flag is essential; it causes the kernel to output the verifier's complete internal reasoning, including the register types and ranges tracked at each instruction, the constraints on memory offsets, and the specific reasoning for any rejection. These logs are piped to a file for post-analysis and evidence documentation.

After successful loading, attaching the program to a network interface is straightforward:

```
ip link set dev enp2s0 xdp obj xdp_synproxy_kern.o sec .text
```

Packets arriving on `enp2s0` are now processed by the eBPF program at the driver level, before entering the kernel's normal networking stack. This is the execution point where vulnerabilities manifest.

Post-verification, the kernel performs internal bytecode transformations and optimizations. These can be inspected via the *xlated* dump:

```
bpftool prog dump xlated name my_prog > xlated.dump
```

The xlated dump shows the bytecode as it exists in kernel memory after the verifier has processed it. This proves whether the vulnerability survived verification intact or was transformed/sanitized. Runtime traces and kernel output confirm execution and behavior.

5.4 Runtime Observation and Debugging

5.4.1 Kernel Tracing with trace_pipe

eBPF debug output uses the `bpf_printk` macro, which writes messages to the kernel trace buffer. These can be observed in real-time via:

```
cat /sys/kernel/debug/tracing/trace_pipe
```

During PoC execution, trace output confirms that specific code paths are executing and vulnerabilities are being triggered. Example output from vulnerability testing:

```
[argcomp]:  5.6a - csum
[taintnoproto]:  5.39 - OOB index:  18
[taintsink]:  5.46b - Copy length:  256
```

Each line corresponds to a vulnerability test; the messages confirm that the vulnerable code executed and reached the instrumentation point. This provides immediate feedback during exploitation attempts.

5.5 Proof-of-Concept Development

5.5.1 High-Level Packet Crafting with Scapy

For the **simpler ABI violation vulnerabilities** (5.06a, 5.06b, 5.06d), PoCs use **Python with the Scapy library** for straightforward packet construction and sending. A typical exploit:

```
from scapy.all import IP, TCP, send
target_ip = detect_vm_ip() # Auto-detect via virsh
pkt = IP(dst=target_ip) / TCP(dport=80, flags="S")
send(pkt, count=5, verbose=0)
```

This approach offers **simplicity and automation**: IP and TCP headers are automatically generated, checksums are computed by Scapy, and the packet is sent at the raw layer. Scapy handles the complexity of socket setup and header formatting. All ABI-mismatch PoCs include **automatic IP detection** using `virsh` queries to find the target VM's IP, eliminating the need for manual IP configuration. The PoCs require **sudo** to send raw packets.

5.5.2 Raw Sockets for Precise Exploit Crafting

For the **more complex taint-tracking vulnerabilities** (5.39, 5.46b), which require **precise control over packet fields** and **crafted sequence numbers** or **malformed TCP headers**, PoCs use **raw sockets** with low-level **struct packing**:

```
s = socket.socket(socket.AF_INET, socket.SOCK_RAW, socket.IPPROTO_TCP)
tcp_header = struct.pack('!HHLLBBHHH', src_port, dst_port, seq, ack, ...)
tcp_check = checksum(pseudo_header + tcp_header)
s.sendto(packet_bytes, (vm_ip, 0))
```

This allows:

- **Precise sequence number crafting** (5.39 uses bit-shifted values to exploit endianness truncation in the verifier-bypassed bounds check)
- **Malformed TCP header fields** (5.46b uses `doff=15` to claim a 60-byte header while sending 40 bytes, triggering the buffer overflow)
- **Manual checksum calculation** for valid packets that pass kernel validation
- **Auto-detection** of both attacker IP (local interface) and target VM IP via `virsh` integration

All raw socket PoCs include **error handling**, **time delays** between packet sends to allow the XDP program to process them, and **instructions to monitor `trace_pipe`** for verifying successful exploitation. All PoCs require **sudo** to use `IPPROTO_TCP` raw sockets.

5.6 Testing Session Automation: tmux

The **start_session.sh** script was inherited from the previous research team and subsequently enhanced to automate `vmlinux.h` extraction and adapt to VM network configuration (see Section 4.6 for details). It creates a tmux session with three panes:

Pane	Purpose
1. Loader output	Shows XDP program attachment status
2. Netcat server	Listens on port 80 to accept connections
3. Kernel trace	Real-time `trace_pipe` output

Table 5.1: tmux session structure for testing

This setup allows monitoring program load status, server state, and kernel debug output simultaneously.

5.7 Dependency Summary

All dependencies are pre-installed in the provisioned VM. On a fresh Ubuntu 24.04 system, install:

```
apt-get update
apt-get install -y clang llvm llvm-tools bpf-tools linux-headers-6.8 netcat-openbsd
tcpdump iproute2 tmux git make python3-scapy
```

5.8 Kernel and Target

- Linux Kernel LTS 6.8
- XDP SynProxy (selftests) as target program

5.9 Tooling

- `clang/llvm` for compilation and `llvm-objdump` for bytecode inspection
- `bpftool` for load, verifier logs, and `xlated/jited` dumps
- `trace_pipe` for runtime evidence
- PoCs in Python (Scapy or raw sockets) for traffic generation

5.10 Workspace Structure

Per-vulnerability artifacts are stored in `src/exploits/<vuln_id>/` with dedicated READMEs, logs, and proofs. Repository-level setup notes are documented in `src/MODs.md`.

6 Vulnerability Overview

6.1 Selection Criteria

From the prior team's assessment of 60+ potential vulnerabilities, five were selected based on:

1. **High verifier bypass probability**: Previously classified as "exploitable" or "limited"
2. **Representativeness**: Cover multiple vulnerability classes (ABI, type confusion, bounds checking, taint tracking)

3. **Practical feasibility**: Can be triggered via network packets within the test infrastructure
4. **Evidence potential**: Clear stages from bytecode to runtime where impact is observable

6.2 Vulnerability Summary Table

ID	Vulnerability Name	ISO Rule	Class
5.06a	Function Pointer Type Mismatch	5.06	ABI (Application Binary Interface) Mismatch
5.06b	Wrong Argument Count	5.06	ABI (Application Binary Interface) Mismatch
5.06d	Wrong Argument Types	5.06	ABI (Application Binary Interface) Mismatch
5.39	Unprototyped Function Pointer	5.39	Type Confusion (Stack OOB Write)
5.46b	Tainted Length (Packet Buffer)	5.46	Bounds Checking (Packet OOB Write)

6.3 Vulnerability Classes

6.3.1 ABI Mismatch Vulnerabilities (5.06a, 5.06b, 5.06d)

These three vulnerabilities exploit discrepancies between function signatures and actual function call invocations.

ISO-IEC Rule 5.06 Background

Rule 5.06 specifies: *"Do not declare pointers to functions with a type that differs from the function definition."*

Violating this rule means a function pointer is declared with one signature (e.g., `int (*fp)(int)`) while the actual function has a different signature (e.g., `int func(int, int, int)`). When calling through the pointer, mismatched numbers and types of arguments are passed, violating ABI expectations.

Why This Matters for eBPF

The eBPF verifier must validate that:

1. Function pointers are declared with correct types
2. Calls through pointers pass arguments of the correct count and type
3. Registers align correctly with the expected function signature (x86-64 ABI (Application Binary Interface))

If the verifier fails to catch signature mismatches, it may allow registers to be used as the wrong type (e.g., uninitialized register passed as pointer), extra arguments to overwrite adjacent stack or registers, or type truncation or sign-extension bugs (e.g., 64-bit pointer passed as 32-bit int).

Classification of 5.06a, 5.06b, 5.06d

Based on prior analysis and practical testing, vulnerability 5.06a represents type incompatibility where the function expects a different return type, 5.06b involves wrong argument counts where calls are made with more arguments than declared, and 5.06d involves wrong argument types such as passing an int where a long is expected.

All three are **runtime triggers** — the verifier accepts the code despite the mismatch, and runtime behavior is observable via kernel trace output. However, they do not constitute true

memory corruption in the test environment (the vulnerability is in register alignment, not buffer overflow).

6.3.2 Type Confusion with Stack OOB Write (5.39 taintnoproto)

ISO-IEC Rule 5.39 Background

Rule 5.39: *"Do not create pointers to functions with an implicit return type."*

In this violation, a function pointer is declared without a complete prototype (missing argument types). The pointer is called with specific arguments, but the compiler and verifier cannot properly validate the call because the prototype is incomplete.

The 5.39 Exploit Mechanism

The XDP SynProxy vulnerability (5.39) combines:

1. A TCP sequence number (64-bit, attacker-controlled via SYN packet)
2. An array of `u16` values on the stack
3. An unprototyped function pointer call that uses the sequence number as an array index

If the sequence number is large (e.g., 18, 25, etc.), the array access goes out-of-bounds and writes to adjacent stack memory.

Classification

5.39 is an EXPLOITABLE vulnerability (not just a runtime trigger). The **out-of-bounds write** targets the eBPF program's local stack frame, allowing an attacker who controls the sequence number to determine which eBPF-local stack location is overwritten. However, due to the eBPF sandbox model, such corruption is limited to the XDP handler's execution context and cannot directly compromise kernel memory or enable privilege escalation. The vulnerability is exploitable for Denial of Service or packet processing disruption.

6.3.3 Bounds Checking with Tainted Length (5.46b taintsink)

ISO-IEC Rule 5.46 Background

Rule 5.46: *"Do not apply the sizeof operator to a polymorphic object."*

More broadly, rule 5.46-adjacent violations include using user-controlled (tainted) values for memory copy lengths (`memcpy(dst, src, user_len)`), array indices, and loop bounds.

The 5.46b Exploit Mechanism

The XDP SynProxy vulnerability (5.46b) is:

1. Parsing a TCP header payload length from an incoming packet
2. Using that length directly in a loop that writes to packet buffer fields
3. The destination field is fixed-size (e.g., 6-byte MAC address field)
4. An attacker crafts a packet with a large payload length (e.g., 60 bytes from TCP doff field)
5. Result: Packet buffer overflow, overwriting adjacent packet header fields (MAC source, protocol)

Classification

5.46b is an EXPLOITABLE vulnerability: The **packet-length-based buffer overflow** is directly triggered and controlled by an attacker. The verifier accepts bounds checks on tainted values, allowing the write size to exceed the buffer. Attackers can overflow 54+ bytes past the 6-byte `h_dest` field, corrupting adjacent **packet buffer memory** (within the same packet structure). This overflow is confined to in-kernel packet buffer operations and does NOT directly compromise kernel data structures or enable privilege escalation. The vulnerability demonstrates a verifier gap but has limited real-world impact.

- Direct packet buffer overflow
- Attacker controls the overflow size (via TCP doff field)
- Overwrites adjacent packet fields (MAC source, protocol)
- Confirmed memory write primitive within packet scope only

6.4 Exploitation Chains

6.4.1 5.06a/5.06b/5.06d: Potential Escalation Path

While these are runtime triggers in the current target, they could become exploitable in a chained attack:

1. Trigger the ABI mismatch to observe register/stack state
2. Use information disclosure to leak kernel addresses or structure offsets
3. Combine with a separate vulnerability for full exploitation

6.4.2 5.39: Direct Exploitation

Stack OOB write is confirmed as a memory corruption primitive within the eBPF sandbox. Full exploitation for DoS would require:

1. Knowledge of eBPF stack frame structure
2. Identification of exploitable eBPF-local data structures
3. Triggering specific sequence numbers to corrupt the target

6.4.3 5.46b: Direct Exploitation

Packet buffer overflow provides a confirmed memory write primitive within packet scope:

1. Attacker controls overflow size via crafted TCP Data Offset field
2. Attacker controls overflow data via packet payload contents
3. Corrupts in-kernel packet buffer memory (adjacent header fields)
4. With XDP processing of attacker-controlled packets, the vulnerability is reliably triggerable
5. **NOTE**: Overflow is limited to packet-local memory; does NOT enable kernel-level privilege escalation

6.5 Impact Differentiation: Runtime Triggers vs. Memory Corruption Primitives

A critical distinction emerges when comparing the five vulnerabilities:

6.5.1 Runtime Triggers (Limited Impact): 5.06a, 5.06b, 5.06d

The three ABI mismatch vulnerabilities are **verifier bypasses** but have **limited practical impact** in the XDP SynProxy context:

- **No direct memory corruption**: The mismatched calls do not cause buffer overflows or out-of-bounds writes.
- **No control flow hijacking**: Function pointers still target real, kernel-intended functions (not attacker addresses).
- **Trigger-able but not exploitable**: The vulnerabilities can be triggered via network packets and observed via kernel traces, but they do not yield a usable memory write primitive.
- **Contextual threat**: If similar patterns appeared in code using the mismatched arguments for pointer arithmetic, bounds calculations, or array indexing, they would become more dangerous. In this PoC, they are demonstrations of verifier design gaps rather than exploitable vulnerabilities.

6.5.2 Memory Corruption Primitives (Significant Impact): 5.39, 5.46b

The two taint-tracking vulnerabilities are **confirmed exploitable** and provide **memory corruption capability** with **scope limitations**:

- **5.39 (Stack OOB Write)**: Demonstrated write to out-of-bounds eBPF-local stack locations with attacker-controlled offset (derived from TCP sequence number). **Limited to eBPF sandbox**; cannot compromise kernel memory.
- **5.46b (Packet Buffer Overflow)**: Demonstrated 54-byte overflow beyond a 6-byte field with attacker-controlled data (packet payload). **Limited to packet-local memory** (adjacent packet fields); does not enable kernel-level RCE (Remote Code Execution).
- **Impact within scope**: 5.39 can disrupt XDP packet processing; 5.46b can corrupt packet headers in flight.
- **Reliability**: Both are reliably triggerable via standard network packets; no special conditions are required.

6.5.3 Summary

Vulnerability	Type	Practical Impact in SynProxy
5.06a, 5.06b, 5.06d	Runtime Trigger	Verifier bypass; limited exploitability
5.39	Memory Corruption	Stack OOB write primitive; highly exploitable
5.46b	Memory Corruption	Buffer overflow primitive; highly exploitable

6.6 Next Steps

The following chapters provide detailed analysis of each vulnerability, including:

- Complete source code of the vulnerability patch
- Bytecode and verifier analysis showing that the issue is preserved
- PoC code and runtime evidence
- Assessment of real-world exploitability

7 Vulnerability 5.06a: Function Pointer Type Incompatibility

7.1 Executive Summary

Vulnerability 5.06a is an ABI (Application Binary Interface) mismatch where a function pointer is declared with one signature (taking no arguments) but assigned to and called as a function with a completely different signature (expecting arguments). This violates ISO-IEC Rule 5.06 and represents a **verifier bypass** rather than a directly exploitable memory corruption.

ISO Rule Violated

ISO-IEC Rule 5.06: "Do not declare pointers to functions with a type that differs from the function definition"

Severity

MEDIUM: Verifier bypass confirmed. No direct memory corruption in this context, but demonstrates systematic ABI enforcement gap in the verifier.

7.1.1 Why This Vulnerability Matters

1. **Verifier Gap**: The eBPF verifier does not validate function pointer type compatibility
2. **ABI Violation**: Function arguments are passed in fixed registers (R1-R5), but type mismatches mean the caller and callee disagree on what those values represent
3. **Systemic Risk**: While limited in this specific code context, similar patterns in pointer arithmetic or array indexing could become dangerous

7.2 The Vulnerable Code Pattern

7.2.1 Vulnerable Code (Simplified)

```
/* Forward declaration with wrong signature */
__u16 (*fp_wrong_type)(); /* Takes no arguments */

/* Assignment to a function expecting different signature */
fp_wrong_type = csum_fold; /* csum_fold expects __u32 */

/* Call with incompatible arguments */
__u16 csum_result = fp_wrong_type(0x12345678, 0x9abcdef0);
bpf_printk("[argcomp]:  5.6a - csum:  %u", csum_result);
```

7.2.2 Why This Is Vulnerable

1. **Declared Type**: The pointer declares '___u16 (*)(void)' takes no arguments
2. **Actual Function**: But it's assigned to 'csum_fold', which expects one '___u32' argument
3. **Called With**: Two arguments ('0x12345678', '0x9abcdef0') are passed
4. **Verifier Gap**: The verifier focuses on memory safety, not ABI (Application Binary Interface) correctness. It doesn't cross-check the declared type against the actual function signature

7.2.3 What Should Prevent This

The verifier should:

- Track function pointer types throughout their lifetime
- Validate that calls through pointers match the declared prototype
- Reject assignments that violate type contracts

Currently, **it does not perform this full validation**, allowing 5.06a to pass.

7.3 Multi-Stage Analysis: Evidence Chain

7.3.1 Stage 1: Source Code (Patch Location)

The vulnerability is introduced via a Git patch:

```
  XDPs/xdp_synproxy/patches/5_06a_argcomp/0001-feat-5.06a-function_pointer-type-incompatibility.pat
```

7.3.2 Stage 2: Bytecode (llvm-objdump)

Using `llvm-objdump -S xdp_synproxy_kern.o`, the compiled eBPF bytecode preserves the vulnerable instruction sequence:

```
;  bpf_printk("[argcomp]:  5.6a - csum:  %u", csum_result);
56:  (b7) r3 = 0x9753    # Load constant 38739
57:  (85) call 0x6    # Call bpf_trace_printk
```

Finding: The constant ‘0x9753‘ (38739) appears in bytecode, proving the vulnerable code path was **not optimized away** by the compiler.

7.3.3 Stage 3: Verifier (bpftool prog load)

Command:

```
sudo bpftool prog load xdp_synproxy_kern.bpf.o /sys/fs/bpf/test_synproxy type
xdp -d
```

Result: The verifier **accepts the program without error**. No rejection, no warning.
Finding: The verifier does not validate function pointer type compatibility. The program passes verification despite the ABI (Application Binary Interface) mismatch.

7.3.4 Stage 4: Xlated Bytecode (bpftool prog dump xlated)

The verifier-processed bytecode:

```
; bpf_printk("[argcomp]: 5.6a - csum: %u", csum_result);
56: (b7) r3 = 38739 # Constant still present
57: (85) call bpf_trace_printk#-115712
```

Finding: The xlated bytecode is nearly identical to the compiled bytecode. The constant and function call **survive verification unchanged**. No guards or safety checks inserted.

7.3.5 Stage 5: Runtime Execution (trace_pipe)

Trigger the vulnerability by sending TCP SYN packets:

```
python3 src/exploits/5_06a_argcomp/exploit_506a.py
```

Kernel trace output:

```
<idle>-0 [000] ..s2. 348.737756: bpf_trace_printk: [argcomp]: 5.6a -
csum: 38739
```

Finding: The constant value ‘38739‘ appears in kernel traces, linking all previous stages together. The vulnerable code executes at runtime.

7.3.6 Summary: Evidence Chain

Stage	Finding
Bytecode	Constant `0x9753` present (not optimized away)
Verifier	No rejection; program accepted
Xlated	Constant and call survive verification
Runtime	Trace shows constant ‘38739‘

Conclusion: The vulnerability is **real, complete, and executes at runtime**.

7.4 Exploitation Analysis

In the current proof-of-concept, the mismatched call passes hardcoded values that are not dereferenced as pointers, so no memory corruption occurs. The function call completes, and

the XDP handler continues normally. However, if similar ABI (Application Binary Interface) mismatches appeared in code that used the mismatched arguments for pointer arithmetic, array indexing, or as size parameters, they could produce invalid memory addresses, enable out-of-bounds access, or create buffer overflow conditions with false bounds. In those contexts, 5.06a would become **directly exploitable**.

7.5 Artifact Evidence

All analysis logs are available in: `src/exploits/5_06a_argcomp/logs/`

- `5_06a_bytecode_analysis.txt`, Full llvm-objdump output
- `5_06a_verifier_log.txt`, Verifier output (bpftool prog load -d)
- `5_06a_xlated_dump.txt`, Xlated bytecode (verifier-processed)

PoC script: `src/exploits/5_06a_argcomp/exploit_506a.py`

8 Vulnerability 5.06b: Wrong Number of Arguments

8.1 Executive Summary

Vulnerability 5.06b is an ABI (Application Binary Interface) mismatch where a function is called with **more arguments than its signature declares**. This violates ISO-IEC Rule 5.06 and represents a **verifier bypass** rather than directly exploitable memory corruption in this context.

ISO Rule Violated

ISO-IEC Rule 5.06: "For a call to a function without a function prototype in scope, the number of arguments does not equal the number of parameters"

Severity

MEDIUM: Verifier bypass confirmed. Extra arguments are ignored by the callee, but register state is perturbed. Potential information disclosure vector.

8.1.1 Why This Vulnerability Matters

1. **Verifier Gap**: The eBPF verifier does not validate that the number of arguments matches the function signature
2. **Register Misalignment**: Arguments are passed in fixed registers (R1-R5). Extra arguments leave register state inconsistent
3. **Information Leakage**: If extra arguments contain sensitive kernel values, they may be disclosed to attackers

8.2 The Vulnerable Code Pattern

8.2.1 Vulnerable Code (Simplified)

```
/* Forward declaration WITHOUT parameters */
void network_copy_helper();

/* Call with 3 arguments */
__u8 extra_buf[ETH_ALEN] = {0};
network_copy_helper(hdr->eth->h_source,
                    hdr->eth->h_dest,
                    extra_buf);

/* Actual definition takes only 2 arguments */
void network_copy_helper(char *dst, char *src) {
__builtin_memcpy(dst, src, ETH_ALEN);
}
```

8.2.2 Why This Is Vulnerable

1. **Forward declaration**: Has **no parameter list**, '()' means unknown arity
2. **Called with 3 arguments**: Passes values in R1, R2, R3
3. **Function expects 2**: Only consumes R1 and R2
4. **Verifier gap**: Doesn't check that argument count matches; only validates memory safety
5. **Result**: R3 contains uninitialized/garbage register state

8.3 Multi-Stage Analysis: Evidence Chain

8.3.1 Stage 1: Source Code (Patch Location)

The vulnerability is introduced via a Git patch:

```
XDPs/xdp_synproxy/patches/5_06b_argcomp/0001-feat-5.06b-wrong-argument-count.patch
```

8.3.2 Stage 2: Bytecode (llvm-objdump)

Using `llvm-objdump -S xdp_synproxy_kern.o`:

```
;  __builtin_memcpy(dst, src, ETH_ALEN);
61:  (71) r1 = *(u8 *)(r4 +5)
;  ...  memcpy loop operations ...
72:  (73) *(u8 *)(r2 +6) = r1
;  bpf_printk("[argcomp]:  5.6b - network copy called");
73:  (18) r1 = 0x0 ll
76:  (85) call 0x6
```

Finding: The bytecode preserves the full call sequence including memory operations and the argument-count-mismatch signal. Not optimized away.

8.3.3 Stage 3: Verifier (bpftool prog load)

Command:

```
sudo bpftool prog load xdp_synproxy_kern.bpf.o /sys/fs/bpf/test_synproxy type
xdp -d
```

Result: The verifier **accepts the program without error**.
Finding: No rejection, no warning. The verifier does not validate argument count matching.

8.3.4 Stage 4: Xlated Bytecode (bpftool prog dump xlated)

```
61:  (71) r1 = *(u8 *)(r4 +5)
72:  (73) *(u8 *)(r2 +6) = r1
73:  (18) r1 = map[id:7][0]+0
76:  (85) call bpf_trace_printk#-115712
```

Finding: Xlated bytecode is nearly identical to compiled bytecode. The call **survives verification unchanged**.

8.3.5 Stage 5: Runtime Execution (trace_pipe)

Trigger the vulnerability:

```
python3 src/exploits/5_06b_argcomp/exploit_506b.py
```

Kernel trace output:

```
<idle>-0 [000] ..s2.  348.738659:  bpf_trace_printk:  [argcomp]:  5.6b -
network copy called
```

Finding: The signal appears repeatedly in kernel traces, **linking all stages together**. Code executes at runtime.

8.4 Exploitation Analysis

At runtime, an extra argument is passed in R3 (caller setup), but the function consumes only R1 and R2 (callee setup), so R3 is ignored and no immediate memory corruption occurs. The extra argument is ignored by the callee, preventing buffer overflow, pointer dereference, or stack corruption in the current context. However, if the calling context later inspects R3 or other register state, it might find unexpected values. In other contexts, if the mismatched function expected to use the extra arguments, it could access kernel memory via a pointer in R3, use a size parameter in R3 for bounds checking, or perform arithmetic on R3 leading to invalid offsets. In those cases, 5.06b would become **directly exploitable**.

8.5 Artifact Evidence

All analysis logs are available in: `src/exploits/5_06b_argcomp/logs/`

- `5_06b_bytecode_analysis.txt`, Full llvm-objdump output
- `5_06b_verifier_log.txt`, Verifier output (bpftool prog load -d)

- `5_06b_xlated_dump.txt`, Xlated bytecode (verifier-processed)

PoC script: `src/exploits/5_06b_argcomp/exploit_506b.py`

9 Vulnerability 5.06d: Wrong Argument Types

9.1 Executive Summary

Vulnerability 5.06d is an ABI (Application Binary Interface) mismatch where a function is called with **mismatched argument types**, a 16-bit value is passed where a 64-bit value is expected. This violates ISO-IEC Rule 5.06 and represents a **type confusion** that could lead to memory corruption if the mismatched value is used for pointer arithmetic or size calculations.

ISO Rule Violated

ISO-IEC Rule 5.06: "Expression that denotes the called function is not type-compatible with the function definition"

Severity

MEDIUM: Verifier bypass confirmed. Limited impact in this context due to arithmetic-only usage, but could enable memory corruption if value were used for indexing or pointer arithmetic.

9.1.1 Why This Vulnerability Matters

1. **Verifier Gap**: The eBPF verifier does not enforce type width matching for function arguments
2. **Uninitialized Bits**: Only the lower 16 bits are initialized from packet data; upper 48 bits are garbage
3. **Silent Type Confusion**: If the function uses this value for address calculation, could access wrong memory

9.2 The Vulnerable Code Pattern

9.2.1 Vulnerable Code (Simplified)

```
/* Forward declaration without parameters */
long helper_function();

/* Call with int argument */
int int_value = (int)bpf_ntohs(hdr->tcp->window);
/* int = 16-bit TCP window */
long result = helper_function(int_value);
/* Called with int, expects long */
bpf_printk("[argcomp]:  5.6d - math result:  %ld", result);

/* Actual definition expects long (64-bit) */
long helper_function(long x) {
                            return x < 0 ?  -x :  x;
}
```

9.2.2 Why This Is Vulnerable

1. **16-bit TCP window** is loaded from packet into R1
2. **Type casting to int** (32-bit), only lower bits valid, upper bits garbage
3. **Function expects long** (64-bit), expects full 64-bit register value
4. **No sign/zero-extension**: Compiler doesn't insert bounds conversion
5. **Verifier accepts**: Doesn't validate type width compatibility
6. **Result**: Function receives contaminated value with uninitialized upper bits

9.3 Multi-Stage Analysis: Evidence Chain

9.3.1 Stage 1: Source Code (Patch Location)

The vulnerability is introduced via a Git patch:

```
XDPs/xdp_synproxy/patches/5_06d_argcomp/0001-feat-5.06d-wrong-argument-types.patch
```

9.3.2 Stage 2: Bytecode (llvm-objdump)

Using `llvm-objdump -S xdp_synproxy_kern.o`:

```
;  int int_value = (int)bpf_ntohs(hdr->tcp->window);
53:  (69) r1 = *(u16 *)(r7 +14)
54:  (dc) r1 = be16 r1
55:  (85) call pc+824
;  bpf_printk("[argcomp]:  5.6d - math result:  %ld", result);
```

Interpretation:

- Line 53: Load 16-bit TCP window field into R1
- Line 54: Convert from big-endian to native endian
- Line 55: Call helper function with R1 as argument

Critical: Only lower 16 bits are initialized; upper 48 bits are garbage
Finding: Bytecode shows the 16-bit load followed by the function call. No zero-extension or sign-extension instructions. The 48-bit garbage survives compilation.

9.3.3 Stage 3: Verifier (bpftool prog load)

Command:

```
sudo bpftool prog load xdp_synproxy_kern.bpf.o /sys/fs/bpf/test_synproxy type
xdp -d
```

Result: The verifier **accepts the program without error**.
Finding: No type mismatch detected. Verifier does not validate type width matching for function arguments.

9.3.4 Stage 4: Xlated Bytecode (bpftool prog dump xlated)

```
53:  (69) r1 = *(u16 *)(r7 +14)
54:  (dc) r1 = be16 r1
55:  (85) call pc+824
```

Finding: Xlated bytecode is identical to compiled bytecode. **No bounds guards inserted**. The type mismatch survives verification unchanged.

9.3.5 Stage 5: Runtime Execution (trace_pipe)

Trigger the vulnerability:

```
python3 src/exploits/5_06d_argcomp/exploit_506d.py
```

Kernel trace output:

```
<idle>-0 [000] ..s2.  348.739616:  bpf_trace_printk:  [argcomp]:  5.6d - math
result:  8192
```

Finding: The trace shows ‘8192‘ (typical TCP window size). The computation completes despite the type mismatch, **linking all stages together**. Code executes at runtime with contaminated value.

9.4 Exploitation Analysis

At runtime, the TCP window field (16-bit) is loaded into R1, and the upper 48 bits of R1 contain garbage or uninitialized data. The function call passes R1 as a 64-bit argument, so the called function receives `0x[GARBAGE]0000[WINDOW_VALUE]` and uses this mixed value in arithmetic. In the current proof-of-concept, the value is used only in arithmetic (`return x < 0 ? -x : x`), where garbage bits don't cause an exception and the function returns successfully with no

memory corruption, though the **result is semantically wrong** if the garbage bits affect the sign bit or magnitude. However, if the mismatched value were used for array indexing, pointer arithmetic, or bounds checking, the garbage bits could make the index huge (causing out-of-bounds access), create an invalid address (enabling kernel memory write), or bypass bounds checks with a contaminated size parameter (enabling buffer overflow). In those contexts, 5.06d becomes **directly exploitable** for memory corruption.

9.5 Artifact Evidence

All analysis logs are available in: `src/exploits/5_06d_argcomp/logs/`

- `5_06d_bytecode_analysis.txt`, Full llvm-objdump output
- `5_06d_verifier_log.txt`, Verifier output (bpftool prog load -d)
- `5_06d_xlated_dump.txt`, Xlated bytecode (verifier-processed)

PoC script: `src/exploits/5_06d_argcomp/exploit_506d.py`

10 Vulnerability 5.39: Unprototyped Function Pointer (Stack OOB Write)

10.1 Executive Summary

Vulnerability 5.39 is a **confirmed memory corruption vulnerability** combining an unprototyped function pointer (ISO-IEC Rule 5.39 violation) with a **tainted array index derived from the TCP sequence number**, enabling **out-of-bounds writes to the eBPF-local stack frame**. This is directly exploitable but **sandbox-limited**, corruption cannot escape the eBPF context to compromise the kernel.

ISO Rule Violated

ISO-IEC Rule 5.39: "Do not create pointers to functions with an implicit return type"

Severity

MEDIUM-HIGH: Direct memory corruption confirmed. Out-of-bounds stack writes with attacker-controlled offset and value. DoS-capable. **Privilege escalation impossible due to eBPF sandbox isolation**.

10.1.1 Why This Vulnerability Matters

1. **Unprototyped Function Pointer**: Verifier loses tracking of what the function does and what arguments it accepts
2. **Tainted Array Index**: TCP sequence number is attacker-controlled and used directly as an array index
3. **No Bounds Checking**: Verifier cannot prove the index stays within bounds [0-15]
4. **Direct Memory Write**: Can corrupt adjacent eBPF-local stack memory

5. **Sandbox Constraint**: eBPF execution is isolated; corruption cannot reach kernel memory or task credentials

10.2 The Vulnerable Code Pattern

10.2.1 Vulnerable Code (Simplified)

```
/* Target function with range expectation */
struct sample_struct {
                        __u8 array1[16]; /* Expected 0-15 only */
                        __u8 array2[16];
};

static __always_inline void restricted_sink(int i) {
                                                        struct sample_struct s = {};
                                                        bpf_printk("index :  %d", i);
                                                        s.array1[i] = 42; /*
OUT-OF-BOUNDS if i >= 16 */
}

/* Unprototyped function pointer */
void (*pf)() = restricted_sink; /* No prototype!  */

/* Tainted input from TCP packet */
__u32 seq_value = bpf_htons(hdr->tcp->seq) / 1000;
(*pf)(seq_value); /* Verifier loses range info at call boundary */
```

10.2.2 Why This Is Vulnerable

1. **Unprototyped pointer**: ‘void (*pf)()‘, No parameter type info, verifier can’t track argument constraints
2. **Tainted input**: TCP sequence number is attacker-controlled (values 0-$2^{32} - 1$)
3. **Division doesn’t constrain**: ‘seq / 1000‘ is still unbounded (0-4,294,967)
4. **Array size is 16**: Accessing array1[16+] writes beyond buffer into adjacent stack memory
5. **Verifier failure**: Without knowing the expected range [0-15], verifier can’t prevent OOB access

10.3 Multi-Stage Analysis: Evidence Chain

10.3.1 Stage 1: Source Code (Patch Location)

The vulnerability is introduced via a Git patch:

```
XDPs/xdp_synproxy/patches/5_39_taintnoproto/0001-feat-5.39-taintnoproto*.patch
```

10.3.2 Stage 2: Bytecode (llvm-objdump)

Using `llvm-objdump -S xdp_synproxy_kern.o`:

```
;  (*pf)(bpf_htons(hdr->tcp->seq)/1000);
139:  (61) r3 = *(u32 *)(r8 +4) # Load TCP seq
140:  (dc) r3 = be16 r3 # Byte-order swap
141:  (37) r3 /= 1000 # Division (unbounded)
;  bpf_printk("index :  %d", i);
142:  (18) r1 = 0x18 ll
145:  (85) call 0x6 # Call with tainted index in R3
;  s.array1[i] = 42;
149:  (73) *(u8 *)(r10 -80) = r3 # STORE at offset -80 (UNSAFE!)
```

Interpretation: - R3 is loaded from packet (line 139-141) - No bounds check on R3 - Store instruction uses R3 as an offset (line 149) - If R3 $\geq$ 16, this writes beyond the array buffer
Finding: Bytecode shows the unprototyped call with tainted index. Not optimized away.

10.3.3 Stage 3: Verifier (bpftool prog load)

Command:

```
sudo bpftool prog load xdp_synproxy_kern.bpf.o /sys/fs/bpf/test_synproxy type
xdp -d
```

Result: The verifier **accepts the program without error**.
Finding: No rejection for the tainted array index. The unprototyped function call breaks taint tracking.

10.3.4 Stage 4: Xlated Bytecode (bpftool prog dump xlated)

```
139:  (61) r3 = *(u32 *)(r8 +4)
140:  (dc) r3 = be16 r3
141:  (37) r3 /= 1000
149:  (73) *(u8 *)(r10 -80) = r3 # Unsafe store still present
```

Finding: The xlated bytecode is nearly identical to compiled bytecode. **No bounds check inserted**. The vulnerable store survives verification unchanged.

10.3.5 Stage 5: Runtime Execution (trace_pipe)

Trigger the vulnerability:

```
python3 src/exploits/5_39_taintnoproto/poc_539_exploit.py
```

Kernel trace output:

```
<idle>-0 [000] ..s2.  348.737756:  bpf_trace_printk:  [5.39]:  index:  16
<idle>-0 [000] ..s2.  348.738659:  bpf_trace_printk:  [5.39]:  Content:  42
<idle>-0 [000] ..s2.  348.739616:  bpf_trace_printk:  [5.39]:  index:  17
<idle>-0 [000] ..s2.  348.740573:  bpf_trace_printk:  [5.39]:  Content:  42
<idle>-0 [000] ..s2.  348.741530:  bpf_trace_printk:  [5.39]:  index:  25
<idle>-0 [000] ..s2.  348.742487:  bpf_trace_printk:  [5.39]:  Content:  42
```

Finding: The trace shows indices 16, 17, 25 (all ≥ 16, causing OOB writes) and confirms the write value (42). **Links all stages together**. Vulnerability executes at runtime.

10.4 Exploitation Analysis

Memory corruption has been confirmed: the verifier accepts the program, the bytecode preserves the vulnerability, the xlated bytecode has no guards, runtime executes **out-of-bounds writes**, the attacker controls the **index** (via TCP sequence number), and the attacker controls the **write value** (fixed at 0x42).
The ‘array1[16]‘ buffer is only **16 bytes** (indices 0-15 valid), so writing to indices 16-25 **overwrites 10 bytes of adjacent memory** into ‘array2[0-9]‘, modifying adjacent eBPF-local variables. For example, index 25 with value 0x42 writes to offset 25, corrupting 10 bytes into adjacent memory.
The vulnerability can **crash the XDP handler** via corrupted stack frame, cause **kernel panic** if corruption affects critical control structures, or **disable network processing** on the interface, and it is **reliable** because the attacker controls the index value (TCP sequence number), any SYN packet can trigger it, and multiple packets can trigger multiple OOB writes.

However, **privilege escalation is impossible** due to **eBPF sandbox constraints**: execution is isolated from kernel memory, the eBPF stack is separate from kernel stack, and corrupted return addresses affect only the eBPF execution context (not kernel), so memory corruption is **eBPF-local only** and not kernel-level compromise.

10.5 Artifact Evidence

All analysis logs available in: `src/exploits/5_39_taintnoproto/logs/`

- `5_39_bytecode_analysis.txt`, Full llvm-objdump output
- `5_39_verifier_log.txt`, Verifier output (bpftool prog load -d)
- `5_39_xlated_dump.txt`, Xlated bytecode (verifier-processed)

PoC script: `src/exploits/5_39_taintnoproto/poc_539_exploit.py`

11 Vulnerability 5.46b: Tainted Length (Packet OOB Write)

11.1 Executive Summary

Vulnerability 5.46b is a **confirmed memory corruption vulnerability** where an attacker-controlled **tainted packet field (TCP Data Offset)** is used directly as a loop counter in a memory write operation, causing a **buffer overflow within the in-kernel packet buffer**.

The corruption writes to adjacent **packet-local memory** (Ethernet header fields), not kernel data structures.

ISO Rule Violated

ISO-IEC Rule 5.46: "Do not apply the sizeof operator to a polymorphic object" (and related: tainted values in sinks)

Severity

MEDIUM: Direct memory corruption confirmed, but **scope-limited to packet-buffer memory**. Overwrites adjacent packet fields (MAC addresses), not kernel structures. **No privilege escalation possible**.

11.1.1 Why This Vulnerability Matters

1. **Tainted Packet Field**: TCP Data Offset (doff) is attacker-controlled
2. **No Validation**: Value is used directly without bounds checking
3. **Fixed-Size Buffer**: Destination MAC address buffer is only 6 bytes
4. **Verifier Gap**: Doesn't enforce field-level bounds checking within packet structures
5. **Scope Limitation**: Overflow stays within packet-local memory, not kernel memory

11.2 The Vulnerable Code Pattern

11.2.1 Vulnerable Code (Simplified)

```
/* Fixed-size buffer for MAC destination (6 bytes standard) */
unsigned char h_dest[6];

/* Get tainted length from packet TCP header */
__u32 tainted_length = hdr->tcp->doff * 4;
/* doff is 4-15 (4-bit field), so length is 20-60 bytes */
bpf_printk("[taintsink]:  Tainted length %u", tainted_length);

/* Use tainted length in a memory write loop (NO VALIDATION!) */
for (i = 0; i < tainted_length; i++) {
                                      h_dest[i] = /* packet_data[i] */;
/* BUFFER OVERFLOW if tainted_length > 6 */
}
```

11.2.2 Why This Is Vulnerable

1. **Fixed-size buffer**: `h_dest` is **only 6 bytes** (standard Ethernet MAC address)
2. **Tainted length**: `doff * 4` is attacker-controlled via TCP Data Offset field
3. **Range**: TCP doff is a 4-bit field (values 4-15), so `doff * 4` = 20-60 bytes
4. **No validation**: Code directly uses tainted value as loop counter
5. **Overflow**: Writing 60 bytes to a 6-byte buffer = **54-byte overflow** into adjacent memory

11.3 Multi-Stage Analysis: Evidence Chain

11.3.1 Stage 1: Source Code (Patch Location)

The vulnerability is introduced via a Git patch:

```
XDPs/xdp_synproxy/patches/5_46b_taintsink/0001-feat-5.46*.patch
```

11.3.2 Stage 2: Bytecode (llvm-objdump)

Using `llvm-objdump -S xdp_synproxy_kern.o`, the compiled bytecode contains an **unrolled loop** writing 60 times:

```
;  for (i = 0; i < tainted_length; i++) {
;   h_dest[i] = i;
56:  (71) r1 = *(u8 *)(r8 +18) # Load loop counter i
57:  (73) *(u8 *)(r2 -80) = r1 # Store at offset -80+i
58:  (85) call bpf_trace_printk # Signal:  Wrote value at idx
;  ...  (repeated 60 times for doff=15) ...
```

Interpretation: Bytecode shows 60 store instructions (one for each value in the loop). This confirms the compiler **did not optimize away** the loop unrolling despite the unsafe length value.
Finding: The full 60-iteration loop is preserved in bytecode.

11.3.3 Stage 3: Verifier (bpftool prog load)

Command:

```
sudo bpftool prog load xdp_synproxy_kern.bpf.o /sys/fs/bpf/test_synproxy type
xdp -d
```

Result: The verifier **accepts the program without error**.
Finding: Verifier does not reject the 60-byte write to a 6-byte buffer. Field-level bounds checking missing.

11.3.4 Stage 4: Xlated Bytecode (bpftool prog dump xlated)

The xlated bytecode still contains all 60 store instructions:

```
56:  (71) r1 = *(u8 *)(r8 +18)
57:  (73) *(u8 *)(r2 -80) = r1
58:  (85) call bpf_trace_printk
;  ...  all 60 stores preserved ...
```

Finding: Xlated bytecode shows **all 60 store instructions are preserved unchanged**. No verifier-inserted bounds checks. Vulnerability survives verification.

11.3.5 Stage 5: Runtime Execution (trace_pipe)

Trigger the vulnerability with TCP doff=15 (maximum):

```
python3 src/exploits/5_46b_taintsink/5_46b_overflow.py
```

```

hdr->eth->h_source differs
```

Finding: The trace confirms: 1. Tainted length is 60 (doff=15) 2. All 60 writes execute (indices 0-59) 3. MAC source field is corrupted (comparison detects difference)
Links all stages together. Vulnerability executes at runtime.

11.4 Exploitation Analysis

Memory corruption has been **confirmed**: the verifier accepts the program, the bytecode preserves the 60-byte loop, the xlated bytecode has no bounds guards, runtime executes all 60 writes, the attacker controls the length (via TCP data offset), and adjacent memory is corrupted with the MAC source address overwritten.

Packet memory layout shows that the `h_dest` buffer is **6 bytes** (indices 0-5), `h_source` is 6 bytes (indices 6-11), and `h_proto` is 2 bytes (indices 12-13). With **doff=15 (60-byte write)**, bytes 0-5 are written to `h_dest` (intended), bytes 6-11 overflow to `h_source` (first overflow), bytes 12-13 overflow to `h_proto` (second overflow), and bytes 14-59 write beyond the packet header (third overflow).

The impact is **scope-limited**: writes stay within the packet buffer structure (not kernel stack), the overflow cannot reach kernel memory, the attacker cannot modify task credentials or eBPF context, and while the packet may be corrupted, network processing continues with limited DoS potential.

While **direct exploitation for kernel compromise is impossible** due to eBPF sandbox constraints—execution is isolated from kernel memory, the eBPF stack is separate from kernel stack, and corrupted data affects only packet-local memory, not kernel control flow—this vulnerability demonstrates a **critical verifier gap**: the verifier doesn't enforce field-level bounds and only checks packet-level safety, representing a **systematic gap in bounds checking** that affects all packet buffer field access patterns.

The vulnerability is **exploitable within packet-buffer scope**, but the eBPF sandbox prevents kernel-level compromise.

11.5 Artifact Evidence

All analysis logs available in: `src/exploits/5_46b_taintsink/logs/`

- `5_46b_bytecode_analysis.txt` — Full llvm-objdump output (all 60 stores)
- `5_46b_verifier_log.txt` — Verifier output (bpftool prog load -d)

- `5_46b_xlated_dump.txt` — Xlated bytecode with all 60 store instructions

PoC script: `src/exploits/5_46b_taintsink/5_46b_overflow.py`

12 Conclusion and Findings

12.1 Summary of Findings

This practical exploitation study analyzed five vulnerabilities identified by a prior theoretical assessment. The key finding is a clear **dichotomy in verifier behavior**:

Vulnerability	Class	Classification	Confidence
5.06a	ABI Mismatch	Runtime Trigger	High
5.06b	ABI Mismatch	Runtime Trigger	High
5.06d	Type Mismatch	Runtime Trigger / Limited	High
5.39	Taint + Range	Exploitable (Memory Corruption)	Very High
5.46b	Taint + Bounds	Exploitable (Buffer Overflow)	Very High

Table 12.1: Classification of five analyzed vulnerabilities

12.2 Key Observations Across All Vulnerabilities

The five vulnerabilities analyzed in Chapters 7–11 demonstrate **two critical verifier gaps**. First, the verifier **does not enforce x86-64 ABI compliance** for function pointers, accepting calls with **incompatible type signatures** (5.06a), **mismatched argument counts** (5.06b), and **type-width mismatches** (5.06d). These represent a **systematic verifier gap** affecting all code using function pointers with non-matching signatures.
Second, the verifier **fails to properly track tainted values** (user-controlled data from packet fields) through control flow and into array indices or bounds checks, enabling **out-of-bounds memory access** (5.39) and **buffer overflow** (5.46b).
All five vulnerabilities **survive the complete compilation pipeline** from source code through bytecode, verifier acceptance, xlated transformation, and runtime execution, confirming that **neither LLVM nor the verifier eliminate** or guard against these unsafe code paths.
Runtime triggering is **straightforward**: simple SYN packets trigger the ABI mismatches (5.06a/b/d), crafted packets with specific sequence numbers trigger the array index vulnerability (5.39), and TCP packets with oversized payload lengths trigger the buffer overflow (5.46b), all confirmed by **kernel trace output** showing code path execution, array indices, and data writes.

12.3 Contributions and Validation

This report has documented a comprehensive, practical investigation of eBPF verifier logic flaws on Linux LTS 6.8. The work bridges the gap between theoretical vulnerability assessment and practical exploitation, providing:

1. **Five detailed case studies**: In-depth analysis of real verifier bypasses with complete evidence chains

2. **Reproducible methodology**: A systematic, multi-stage approach to validating eBPF vulnerabilities

3. **Functional PoCs**: Working exploits demonstrating vulnerabilities in a production kernel
4. **Evidence artifacts**: Bytecode, verifier logs, xlated dumps, and runtime traces for each vulnerability
5. **Clear distinction**: Between runtime triggers (ABI (Application Binary Interface) mismatches) and true memory corruption primitives

12.4 Key Findings

12.4.1 The Verifier Has Systematic Gaps

The **eBPF verifier does not enforce** ABI (Application Binary Interface) compliance for function pointers (all architectures), argument type and count matching in function calls, tight bounds checking on tainted (user-controlled) values, or taint propagation through function call boundaries. These are not isolated bugs but **systematic limitations** in the verifier's design.

12.4.2 Real Vulnerabilities Exist

Vulnerabilities 5.39 (**eBPF-local stack OOB write**) and 5.46b (**packet buffer overflow**) are not theoretical. They are confirmed to pass the verifier, confirmed to compile to bytecode that preserves the vulnerability, confirmed to execute at runtime with observable **memory corruption**, and proven memory write primitives with scope limitations: 5.39 is eBPF-sandbox-limited; 5.46b is packet-memory-limited.

12.4.3 Evidence Chain Validation

All five vulnerabilities survive the full pipeline from C source through verification to runtime. Bytecode inspection shows the vulnerable instructions exist, verifier acceptance confirms the verifier does not catch them, xlated dumps prove the vulnerability is not sanitized, and runtime traces prove the vulnerability executes. This chain validates that the vulnerabilities are real, not artifacts of analysis tools or compilation quirks.

12.5 Relationship to Prior Work

This project builds directly on the prior team's theoretical assessment. Where they asked *"Does the verifier accept this rule violation?"*, this work asked *"Can we actually exploit it?"* The prior team's classifications (exploitable, limited, safe) were largely confirmed by this practical work. This work extended their analysis by providing functional PoCs and runtime evidence, quantifying memory corruption (bytes written, offsets, scope), establishing a reproducible test infrastructure, and documenting exploitation scope limitations: 5.39 is eBPF-sandbox-limited (DoS-capable, not RCE (Remote Code Execution)); 5.46b is packet-buffer-limited (not kernel compromise).

12.6 Recommendations

12.6.1 For Linux Kernel Developers

1. **Review and apply** the proposed verifier fixes (ABI (Application Binary Interface) checking, taint propagation)
2. **Expand the eBPF test suite** to cover the identified vulnerability patterns

3. **Consider formal verification** of critical verifier components
4. **Backport verifier fixes** to stable kernel releases

12.6.2 For System Administrators

1. Audit which systems allow eBPF program loading
2. Restrict `CAP_BPF` to only trusted users/services
3. Disable eBPF entirely on systems that don't require it (`kernel.unprivileged_bpf_disabled=1`)
4. Monitor for suspicious eBPF program loads and verify their source
5. Test updates to kernel LTS versions thoroughly before production deployment

12.6.3 For Application Developers Using eBPF

1. **Follow secure coding practices** identified in this report
2. **Avoid function pointers** with implicit prototypes
3. **Use explicit bounds checks** on tainted values from network packets
4. **Have eBPF programs reviewed** by security experts
5. **Test programs** against multiple kernel versions

12.7 Final Thoughts

eBPF is a powerful technology that has revolutionized Linux observability and networking. Its **sandboxed execution model** is crucial to its safety story. However, this work demonstrates that **the sandbox has real gaps**.

The good news:

- The vulnerabilities require **specific conditions** (unprototyped pointers, tainted lengths)
- **Fixes are conceptually straightforward** (better type checking, taint tracking)
- The Linux kernel community has a **track record of rapidly fixing** security issues
- **Formal verification and fuzzing** can prevent similar bugs in the future

The challenge:

- The verifier is **complex and performance-critical**
- Each fix must **not slow down** legitimate programs
- **Backward compatibility** must be maintained
- **False positives** (rejecting safe programs) must be minimized

This report provides a **foundation for addressing** these challenges. With **continued investment in verifier security**, eBPF can become a **fully-trusted sandbox** for arbitrary code in the Linux kernel.

12.8 Repository Artifacts

All findings, PoCs, and evidence are available in the project repository:

- **PoCs**: `src/exploits/5_06a...5_46b/` (Python scripts)
- **Logs**: `src/exploits/<vuln>/logs/` (bytecode, verifier, xlated dumps)
- **Documentation**: `src/exploits/<vuln>/README.md` (per-vulnerability details)
- **Methodology**: `src/README.md` (exploitation workflow)
- **Report**: `report/` (this LaTeX document)

For reproduction instructions and environment setup, see the main `README.md` and `Makefile`.

12.9 Future Work

This research opens several avenues for continued investigation:

1. **Backport Analysis**: Test vulnerabilities against older kernel versions (5.x, 4.x) to determine historical scope
2. **Extended Vulnerability Catalog**: Analyze additional patches from the prior team's 60+ vulnerability catalog
3. **Automated PoC Generation**: Develop tooling to automatically generate exploit packets from verifier log patterns
4. **Formal Verification**: Apply formal methods to verify proposed verifier patches [10, 11]
5. **Cross-Architecture Testing**: Extend testing to ARM64 and RISC-V architectures
6. **Fuzzing Integration**: Integrate findings with eBPF fuzzing frameworks (e.g., Syzkaller)
